Abstract

This paper describes the betatron tune measurement in the Large Hadron Collider (LHC) at the European organization for nuclear research (CERN) including the present hardware and the future possible implementations using the Accelerating Damper Transverse (ADT) acquisitions. The ADT data have to be processed to be able to extract the betatron tune. This paper studies the use of Graphic Processing Units (GPUs) to process bunch position acquisition data.

1 Introduction

In a particle accelerator, the charged particles circulate around the ring and oscillate due to the magnets and the accelerating structures. The accelerating structures, in the LHC supra-conducting cavities apply a strong electrical field that oscillates at the RF frequency (f_0) to particles in order to collect and accelerate particles in bunches inside a frequency bucket.

The particles inside a bucket are oscillating longitudinally along the ring and transversally in the vertical and horizontal plane. The longitudinal oscillations are damped by the beam control system. But the transversal oscillations must be damped by a separate system : the ADT[4, 8].

One of the key parameters of the accelerator is the betatron tune. The betatron tune, Q , is the quotient of the betatron oscillation and the particle frequencies.

$$f_\beta = Q * f_0$$

This value allow us to check if the particle beam is stable and don't reach any dangerous instabilities.

2 Tune measurement in the LHC

In order to measure the betatron tune in an accelerator we use Beam Position Monitors (BPMs). These monitors are able to measure the position of the beam in the vacuum chamber.

2.1 Actual system

In the present setup Beam Instrumentation (BI) group is using their diode-based base-band-tune (BBQ) [2] system to acquire the tune over a certain number of machine turn (256 to 128'000). This can work as a passive instrument or as an on demand system by exciting 12 bunches in the beam with the tune kicker (MKQA). ADT has also been used for tune measurement excitation[3].

In normal operation, as the ADT is active, it is difficult to have a good picture of the excited bunches and make a fine tune measurement : the oscillations created by the MKQA are damped by the ADT. There have been studies to disable the ADT for a certain number of bunches in order to get a better tune measurement[5], but this may not be sufficient.

2.2 Proposed system

The ADT also have BPMs and these can have per bunch measurement[7]. This could allow a much precise measurement. But due to the high amount of data to be processed (estimated to 640 mega bytes per seconds for each BPM) we need dedicated hardware to compute the correct tune[6].

During the 2012 normal operation of the LHC, data will be acquired using the ADT acquisition system and data processing techniques will be tried to asses the modification that will be needed in order to make a reliable betatron tune measurement at a reasonable rate[6].

The current VMEbus implementation has some serious issues in particular the bus is quite slow the data rate of the bus is around 40 megabits per seconds. The data need to either be processed on the acquisition board or to be off-loaded to another computer using the serial link available on the board[1].

2.2.1 DSP on VME board

Digital Signal Processors (DSPs) are able to compute Fast Fourier Transforms (FFTs) at high rate and these are used already in the machine at different places to make high speed feedback loops. The question is : is it fast enough to compute all the FFTs needed, DSPs are two orders of magnitude slower than GPUs. We also would have to develop a completely new system in order to be able to use them, in fact we don't have DSPs in the present ADT. The cost of development and the complexity of the deployment should also be studied.

2.2.2 FPGA pre-processing on VME board

Like in the approach using DSPs on VME boards, the question of computing power is still unsolved. We already have in house experience and we already have a lot of Field-Programmable Gate Array (FPGA) installed in the ADT. But if we want to do it we will have to create a new card able to replace the existing one and to make the computation. This mean create a potential problem in the existing setup. The cost is also to be studied we have to develop a new card, test it and install it in the LHC.

2.2.3 GPU off-board computing

This solution can be integrated easily in the present setup. The present acquisition cards already have a digital output and could be used to transfer the data in another crate that could do the computations. The GPUs are cheap (compare to the price of developing a new VMEbus card) and easily scalable. The GPU should have largely enough computing power to be able to make the FFTs. Another interesting aspect of this solution is the ability to test it using Central Processing Unit (CPU).

3 Estimation of the amount of data

Presently the LHC is working with an interval of 50ns between bunches this correspond to a bunch every 10 buckets. But the Operation (OP) is planning to move to 25ns bunches spacing this would mean 5 buckets between bunches. With the RF frequency (f_0) we can compute the number of acquisitions per seconds.

$$\begin{aligned} \text{for } 50 \text{ ns} : \frac{400.789M}{20} &= 20'039'450 \leq 2^{25} \\ \text{for } 25 \text{ ns} : \frac{400.789M}{10} &= 40'078'900 \leq 2^{26} \end{aligned}$$

This represent the amount of data for one pickup (BPM), in the case of ADT we have two of them per beam and per plane so as the LHC has two rings

and for each ring there are two transversal plane and there are two pickups per plane. This means we still have to multiply this value by eight.

$$\text{for } 50 \text{ ns} : 2^{25} * 8 = 2^{28}$$

$$\text{for } 25 \text{ ns} : 2^{26} * 8 = 2^{29}$$

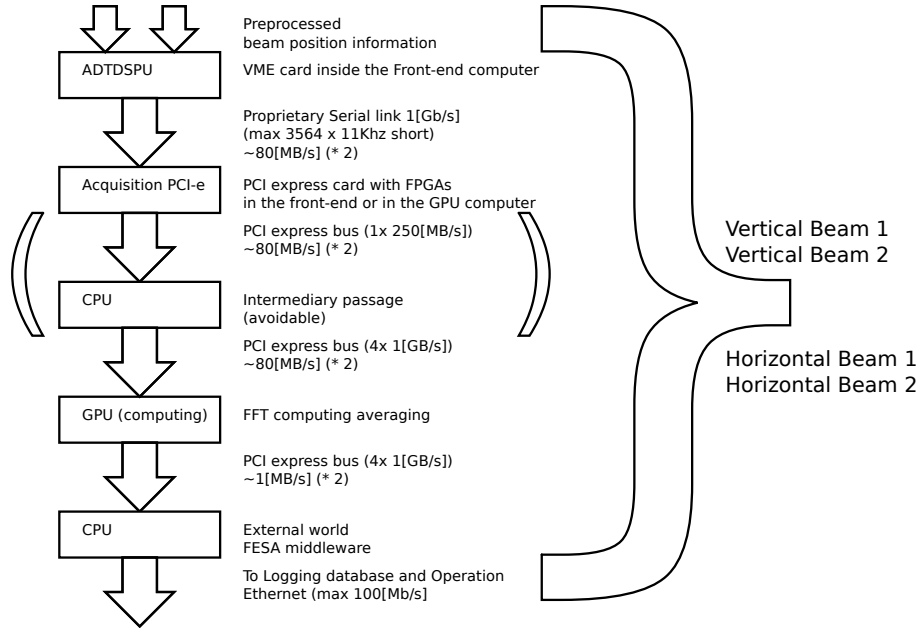

As FFTs on GPUs start to be faster than CPUs around 2^{15} acquisitions it seems interesting to study this kind of system to compute the betatron tune.

4 Measurement with the ADT

In order to check the feasibility of the system and to have a good prototype the first test will be to excite some of the bunches and acquire the betatron tune using the ADT during the end of 2012 run.

A piece of software has been developed that will acquire the bunch by bunch acquisition and compute various algorithm on the data using the CPU and the FFTW library in the CERN infrastructure using Control (CO) group control system and the OP group infrastructure.

5 Proposed implementation

6 Conclusion

This project looks like a nice place to try using GPUs in accelerators. The possibilities are promising and the gain for the stability of the LHC could allow

more physic time. GPUs could prove to be useful and be used in other places in accelerators where computing power is needed.
